Abstract

We present a model that describes states of photon pairs, which have been generated by biexciton cascade decays of self-assembled quantum dots, use of which yields finding that agrees well with experimental result. Furthermore, we calculate the concurrence and determine the temperature behavior associated with so-called entanglement sudden death, that prevents quantum dots emitting entangled photon pairs at raised temperatures. The relationship between the fine structure splitting and the sudden death temperature is also provided.

Entanglement, the intriguing correlations of quantum systems, has found extensive application in the areas of quantum computation [1] and quantum communication [2]. Although this fundamental feature has attracted a lot of attention since the early years of quantum mechanics, it is still far from being completely understood. In recent times, experimentation has found that entanglement within a two-qubit system can disappear abruptly within a finite time during the decoherence process [3–5]. This phenomenon, termed "entanglement sudden death" (ESD), has been demonstrated in optical systems under rather special artificial environments [6, 7].

The generation of entangled photon pairs by using a biexciton cascade process in a single quantum dot (QD) was first proposed by Benson *et al.* [8], and has been recently realized by several groups [9, 10]. In this process, two electrons and two holes are initially generated in the QD (biexciton XX), and then a biexciton photon H_{XX} or V_{XX} is emitted as the dot decays to an exciton (X) state by recombining one electron and one hole. The polarization of the biexciton photon is either horizontal (H) or vertical (V), in accord with the decay into the exciton state X_H or X_V, respectively. After a time delay τ, the other electron and hole recombine to emit an exciton photon H_X or V_X with the same polarization as that of the earlier biexciton photon. When the two recombination paths (H or V)are indistinguishable in frequency, the output is the maximum entangled Bell state $|\Phi\rangle = (|HH\rangle + |VV\rangle)/\sqrt{2}$.

Unfortunately, in QDs, due to the underlying atomic symmetry being C_{2v} rather than C_{4v} [11, 12], the intermediate two exciton state has a small splitting of about several tens of μeV, much larger than the intrinsic width of the emission line ($\sim \mu$eV). This splitting, labeled as S in Figure 1, has conventionally been called the "fine structure splitting" (FSS). Due to this FSS, the actual output is not a pure polarization entangled state, but a state with both polarization and frequency entangled, along with a phase difference between H and V [13],

$$|\Psi\rangle = \frac{1}{\sqrt{2}}(|H_{XX}H_X\rangle + e^{iS\tau}|V_{XX}V_X\rangle). \tag{1}$$

If the frequency is traced over, this state becomes just a mixed state with classical correlations; only when $S \sim 0$ can we achieve an entangled state.

In experiments, there are many methods to tune the FSS, such as by annealing [14], exerting uniaxial stress [15], or applying a magnetic field [16] or an electric field [17]. Meanwhile, various other experiments are designed to erase the frequency information by filtering the photons spectrally [9] or selecting the exciton (X) photon within only a small emission delay relative to the biexciton (XX) photon [13], by which entanglement is greatly enhanced.

In this work, taking the acoustic phonon-assisted transition process into account, we investigated entanglement for photon pairs generated from a QD. A similar ESD, which depends on temperature and FSS, has been found in this process.

A schematic of the biexciton cascade process in a QD is presented in Fig. 1, where the vacuum state (G), the two intermediate exciton states (X_V and X_H), and the biexciton state (XX) are labeled respectively as $|0\rangle \sim |3\rangle$ for convenience.

The QD is initially excited to the biexciton state by a short-pulsed laser, and subsequently evolves freely. Considering the phonon assisted process, the density matrix ($\hat{\rho}$) of this four-level system can be derived using the master equation ($\hbar = 1$) [18],

$$\dot{\hat{\rho}} = -i[\hat{H}_0, \hat{\rho}] + L(\hat{\rho}), \tag{2}$$

where

$$\hat{H}_0 = \sum_{i=0}^{3} \omega_i |i\rangle\langle i|. \tag{3}$$

The dissipation term in the Lindblad form is described by

$$\begin{aligned} L(\hat{\rho}) \;=\; & \frac{1}{2}[\gamma_{32}(|2\rangle\langle 3|\hat{\rho}|3\rangle\langle 2| - |3\rangle\langle 3|\hat{\rho} - \hat{\rho}|3\rangle\langle 3|) \\ & +\gamma_{31}(|1\rangle\langle 3|\hat{\rho}|3\rangle\langle 1| - |3\rangle\langle 3|\hat{\rho} - \hat{\rho}|3\rangle\langle 3|) \\ & +\gamma_{20}(|0\rangle\langle 2|\hat{\rho}|2\rangle\langle 0| - |2\rangle\langle 2|\hat{\rho} - \hat{\rho}|2\rangle\langle 2|) \end{aligned}$$

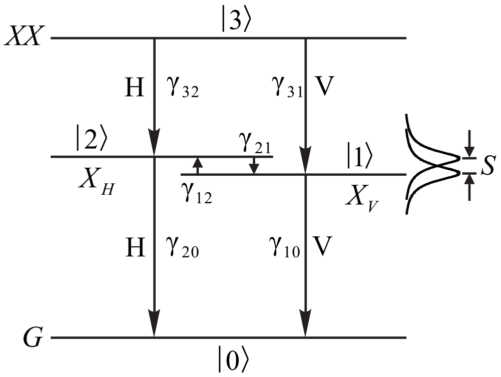

FIG. 1: Energy level schematic of the biexciton cascade process, the ground state G ($|0\rangle$), the two linear polarized exciton state X_H ($|2\rangle$) and X_V ($|1\rangle$) and the biexciton state XX ($|3\rangle$). The spontaneous emission process is denoted by γ_{ij} (γ_{12} and γ_{21} are phonon assisted transition rates).

$$\begin{aligned}&+\gamma_{10}(|0\rangle\langle 1|\hat{\rho}|1\rangle\langle 0| - |1\rangle\langle 1|\hat{\rho} - \hat{\rho}|1\rangle\langle 1|)\\ &+\gamma_{21}(|1\rangle\langle 2|\hat{\rho}|2\rangle\langle 1| - |2\rangle\langle 2|\hat{\rho} - \hat{\rho}|2\rangle\langle 2|)\\ &+\gamma_{12}(|2\rangle\langle 1|\hat{\rho}|1\rangle\langle 2| - |1\rangle\langle 1|\hat{\rho} - \hat{\rho}|1\rangle\langle 1|)],\end{aligned} \tag{4}$$

where γ_{32}, γ_{31}, γ_{20}, γ_{10} are the spontaneous emission rates, while γ_{21} and γ_{12} denote the phonon assisted transition rates between $|1\rangle$ and $|2\rangle$. The phonon absorption rate of the state $|1\rangle$ is $\gamma_{12} = \kappa N_B$ and the emission rate of $|2\rangle$ is $\gamma_{21} = \kappa(N_B + 1)$, where κ is the phonon-QD interaction rate, which is approximately proportional to the cube of the energy splitting S [19], and N_B represents the Bose distribution function of a phonon with energy S, $N_B = [\exp(S/k_BT) - 1]^{-1}$.

This emission process produces radiation in a mixed state, from which the two-photon coincidence measurements single out the polarization density matrix of the photon pair $\hat{\rho}_{\rm pol}$, which is projected onto the subspace spanned by the four basis $\{|H_1H_2\rangle$, $|H_1V_2\rangle$, $|V_1H_2\rangle$, $|V_1V_2\rangle\}$. Its matrix elements, experimentally reconstructed by means of quantum tomography, theoretically read as [20]

$$\begin{aligned}\langle\mu_1\nu_2|\,\hat{\rho}_{\rm pol}\,|\xi_1\zeta_2\rangle \;&=\; \mathcal{A}\int_{t_m}^{t_M} dt \int_{t'_m}^{t'_M} dt'\\ &\times\;\left\langle \sigma^\dagger_{\mu_1}(t)\sigma^\dagger_{\nu_2}(t')\sigma_{\zeta_2}(t')\sigma_{\xi_1}(t)\right\rangle,\end{aligned} \tag{5}$$

where $(\mu, \nu, \xi, \zeta) \in \{H, V\}$, and the σs are the dipole transition operators, $\sigma_{H_1} \equiv |3\rangle\langle 2|$, $\sigma_{V_1} \equiv |3\rangle\langle 1|$, $\sigma_{H_1} \equiv |2\rangle\langle 0|$, $\sigma_{V_2} \equiv |1\rangle\langle 0|$. $\mathcal{A}$ is a normalization factor to ensure that the trace of $\hat{\rho}_{\rm pol}$ is unitary. The limits t_m and t_M (t'_m and t'_M) defined the temporal window related to the detection of the photons from the biexciton cascade process. The emission delay of the exciton photon relative to the biexciton photon, see in Eq. (1), is $\tau \equiv t' - t$. All these correlation functions are computed by applying the quantum regression theorem [21].

Ideally, the polarization density matrix calculated from Eqs. (2) - (5) has the form

$$\hat{\rho}_{\rm pol} = \begin{pmatrix} \rho_{11} & 0 & 0 & \rho_{14} \\ 0 & \rho_{22} & 0 & 0 \\ 0 & 0 & \rho_{33} & 0 \\ \rho_{41} & 0 & 0 & \rho_{44} \end{pmatrix}. \tag{6}$$

All non-diagonal terms except ρ_{14} and ρ_{41} are zero, and the physical reason for this is that the Hamiltonian in Eq.(2) only couples states that share the same excitation labels H and V.

In realistic situations, aside from phonon-induced spin scattering, the system may be affected by some other decoherence processes, such as decay-path distinguishability, background noise, cross dephasing and pure dephasing. However, cross-dephased light has been shown to be weak [22], and photon pair emission in a QD is robust against single photon decoherence being typically limited by pure dephasing [13, 22]. Thus we can ignore cross and pure dephasings in the calculation. Taking the other factors into account, the total density matrix ($\hat{\rho}_{\mathrm{tot}}$) of the photon pair is divided into three parts,

$$\hat{\rho}_{\mathrm{tot}} = \frac{1}{1+g}(\eta\hat{\rho}_{\mathrm{pol}} + (1-\eta)\hat{\rho}_{\mathrm{noc}} + g\hat{\rho}_{\mathrm{noise}}), \tag{7}$$

where $\hat{\rho}_{\mathrm{noc}}$ arises from the FSS-induced distinguishability between the two decay paths, representing the non-overlapping part of the emission lines of excitons X_H and X_V, as shown in Fig. 1. It describes those photon pairs which can be distinguished from the spectra domain, and have only a classical correlation without a phase relationship; hence, the non-diagonal elements of $\hat{\rho}_{\mathrm{noc}}$ are all zero, while the diagonal elements evolve in the same manner as $\hat{\rho}_{\mathrm{pol}}$. The third term $\hat{\rho}_{\mathrm{noise}}$, which describes the background noise, is set as an identity matrix.

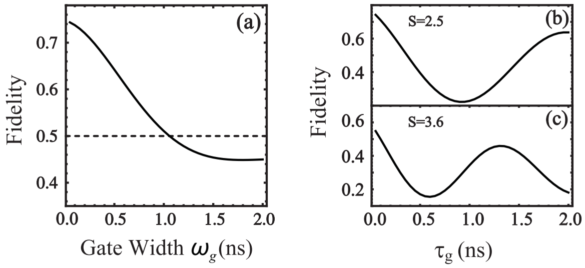

FIG. 2: (a) Fidelity as a function of gate width w_g ($\tau_g = 0$) at $S = 2.5$ μeV. Dashed horizontal line represents the limit for classical behavior. (b) and (c) present the fidelity as a function of τ_g with gate width $w_g = 0.5$ ns for $S = 2.5$ and $S = 3.6$ μeV, respectively.

In Ref. [13], Stevenson *et al.* detected the photon pairs with delays τ in the range $\tau_g \leq \tau \leq (\tau_g + w_g)$ by applying a single timing gate. In this case, the non-diagonal term ρ_{14}

($\rho_{41} = \rho_{14}^*$) has the form of an exponential decay

$$\begin{aligned}\rho_{14} &\propto \int_{\tau_g}^{\tau_g+w_g} d\tau \exp\left[-\Gamma\tau/2 + iS\tau\right] \\ &\propto \frac{e^{(iS-\Gamma/2)\tau_g}}{iS-\Gamma/2}(e^{(iS-\Gamma/2)w_g}-1),\end{aligned} \tag{8}$$

where $\Gamma = \gamma_{20} + \gamma_{10} + \gamma_{12} + \gamma_{21}$. Our results shown in Fig. 2 can explain their experimental behaviors as being a consequence of a maximum fidelity 0.73 of Bell state $|\Phi\rangle$ obtained when gate width was 49 ps. Also, a marked oscillation in fidelity as a function of τ_g was observed, when the same parameters as that in Ref.[13] are chosen: $\gamma_{20} = \gamma_{10} = 1.3$ ns^{-1}, $\gamma_{32} = \gamma_{31} = 1.8$ ns^{-1} (that corresponds to the inverses of the exciton and biexciton lifetimes within a QD), and temperature $T = 10$ K, a value for η, the overlap part of the two exciton spectra, of 0.91 when $S = 2.5\,\mu$eV. To fit the experimental results, we chose $g = 0.45$. When we fix the gate width in Eq. (8), the fidelity as a function of τ_g has a sinusoidal envelop, as evident in Fig. 2 (b) for $S = 2.5\,\mu$eV and (c) for $S = 3.6\,\mu$eV. The frequency of the oscillation increases as the FSS widens. Furthermore, we fix $\tau_g = 0$, and change the gate width w_g, in the long time scale, the integration of Eq. (8) approaches zero. Consequently, the fidelity is below 0.5 (the maximum achievable fidelity for an unpolarized classical state). In contrast, when the gate width is shorter than 1 ns, the fidelity can increase above the classical limit, as shown in Fig. 2 (a).

However, fidelity is insufficient in describing the entanglement properties of the photon pair. To quantify this, a widely used form of entanglement is Wootters' concurrence [23], which is well defined. The concurrence C of a two-particle system is defined as

$$C(\hat{\rho}_{\text{tot}}) = \max\{0, \sqrt{\lambda_1} - \sqrt{\lambda_2} - \sqrt{\lambda_3} - \sqrt{\lambda_4}\}, \tag{9}$$

where λ_i are the eigenvalues of the matrix $\hat{\rho}_{\text{tot}}(\sigma_2 \otimes \sigma_2)\hat{\rho}_{\text{tot}}^*(\sigma_2 \otimes \sigma_2)$ arranged in decreasing order, and $\hat{\rho}_{\text{tot}}$ is defined in Eq. (7).

The result is presented in Fig. 3 where the FSS energy is $2.5\,\mu$eV. As temperature rises, concurrence decreases due to strong phonon induced scattering processes. In Fig. 3 (a), entanglement declines rapidly for large gate widths, that can be ascribed to obtaining more which-path information from the FSS in the energy domain. This is because the Fourier transform of a truncated exponential decay results in a broad natural linewidth of the postselected photons. Long time transition processes between two exciton states also reduce entanglement, as shown in Fig. 3 (b) where w_g is fixed at 0.1 ns.

Under both situations, ESD is observed at high temperatures. It is worth noticing that this ESD is quite different from those in quantum optics experiments [6, 7], where one can alter the initial state to prevent the system from undergoing ESD. In a QD system, the ESD is mainly due to the intrinsic phonon assisted transition process between $|1\rangle$ and $|2\rangle$. Thus, we cannot change the initial state, but FSS can be tuned in experimnet, and we can show that the ESD phenomenon will disappear when the FSS is small and the temperature is low.

Further, the influence of temperature and FSS are investigated, as shown in Fig. 4. The photon pair generated by a QD with large FSS has lower degree of entanglement, that also falls off rapidly. However, for a QD with small FSS, such as $S = 0.5\,\mu$eV, the concurrence decays slightly with temperature, because a tiny phonon assisting emission rate results in a small transition rate in this small-FSS system. Comparing Fig. 4 (a) and (c), for which the evolution time is the only differing parameter, entanglement at low temperature is found to be almost the same for every FSS, although the decreasing rates are apparently faster for longer evolution times (Fig. 4 (c)) and ESD temperatures are lower for larger FSSs. In

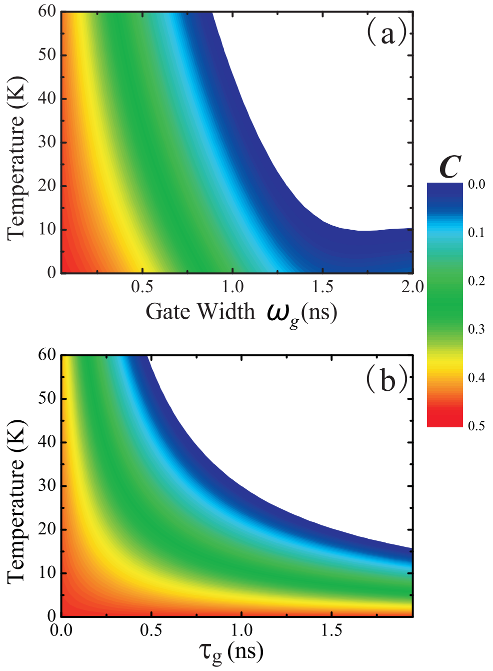

FIG. 3: (Color online). Concurrence as a function of temperature and (a) gate width w_g ($\tau_g = 0$), (b) delay time τ_g ($w_g = 0.1$). The FSS is $2.5\,\mu$eV.

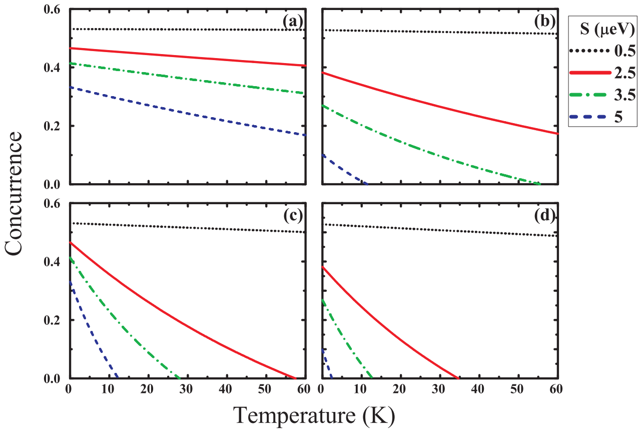

FIG. 4: (Color online). Concurrence as a function of temperature for different FSS energies. The four kinds of line shapes represent that S is 0.5, 2.5, 3.5, and 5 μeV respectively. (a) $w_g = 0.1$ ns and $\tau_g = 0$ ns. (b) $w_g = 0.5$ ns and $\tau_g = 0$ ns. (c) $w_g = 0.1$ ns and $\tau_g = 0.5$ ns. (d) $w_g = 0.5$ ns and $\tau_g = 0.5$ ns.

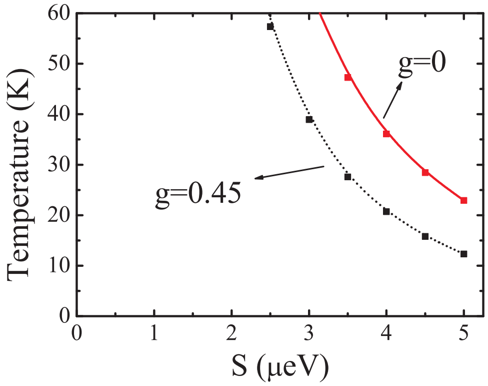

FIG. 5: (Color online). The relationship between the sudden death temperature and splitting S. Gate width $w_g = 0.1$ ns.

Fig. 4 (b), the degree of entanglement is already small at low temperature due to its large gate width, and the reduction rate is faster than that in (a), a fact attributable to a system evolving within the time duration of the gate window. In Fig. 4 (d), the influence of long evolution times and the gate widths are taken into account, so the concurrence initial values at low temperatures are small, and reduction rates are the fastest.

Finally, we show that the observed ESD is independent of background light. In Fig. 5, we present the relationship of sudden death temperature as a function of splitting S for different g, for which we choose $\tau_g = 0.5$ ns and $w_g = 0.1$ ns. Even in the ideal case, i.e. $g = 0$, we still observe ESD. The ESD temperature decreases fast with respect to FSS, owning to the fact that for large FSS, not only is the transition rate between the two exciton states fast, but also the initial degree of entanglement is very small, due to the distinguished part $\hat{\rho}_{\mathrm{noc}}$ being dominant in the total density matrix $\hat{\rho}_{\mathrm{tot}}$. This indicates that a large-FSS QD cannot generate good entangled photon pairs even at low temperatures.

In conclusion, we have calculated the concurrence of photon pairs emitted from quantum dots and considered how temperature and fine structure splitting affect entanglement between a photon pair. An enhancement of entanglement sudden death with temperature has been found. This obviously prevents quantum dots emitting entangled photon pairs at high temperatures. We also point out that this entanglement sudden death is a characteristic of quantum dot systems.
